**Abstract**

This paper describes the design and implementation of version 1.1 of the **FIRE engine**. The **FIRE engine** is a C++ class library implementing finite automata and regular expression algorithms. The algorithms implemented in the toolkit are almost all of those presented in the taxonomies of finite automata algorithms [Wat93a, Wat93b]. The reader is assumed to be familiar with the two taxonomies and with advanced C++ programming techniques.

The toolkit is implemented largely in an object-oriented style, with finite automata and regular expressions being defined as classes. All of the classes and functions in the toolkit are presented in the same format. For each class (or function) the format includes a short description of its behaviour, details of its implementation, and techniques for improving its performance.

# Contents

# 1 Introduction

The **FIRE engine** is a class library implementing finite automata and regular expression algorithms. The algorithms implemented are all of the algorithms presented in the taxonomies of finite automata algorithms [Wat93a, Wat93b]. This paper outlines the design and implementation of the class library, which consists of 9000 lines of C++ code. A number of other toolkits (mostly serving different purposes) are available; they are detailed in [Wat94], which also contains an introduction to the **FIRE engine**.

In order to understand the implementation of the **FIRE engine**, the reader is assumed to be familiar with the taxonomies [Wat93a, Wat93b], and with C++ terminology and programming techniques. An introduction to the C++ language can be found in [Lip91, Str91] (the language reference appears in [Str91, SE90]), while an introduction to C++ programming techniques can be found in [Bud94]. Advanced C++ programming techniques are presented in [Cop92, MeS92, Mur93]. Object-oriented programming, in general, is discussed in [Boo94, Bud91, MeB88].

The most effective way to understand the implementation of the class library is to read the code and the comments embedded within the code. The explanations given in this paper are intended as an outline, to assist in understanding the code.

This paper is structured as follows:

- Part I provides descriptions of all of the foundations classes — those classes used in the implementations of other classes.
- Part II gives descriptions of all classes related to regular expressions and $\Sigma$-algebras.
- Part III gives descriptions of all classes implementing finite automata.
- Part IV presents the functions implementing deterministic finite automata minimization algorithms.

**Acknowledgements:** I would like to thank the following people for their assistance in the preparation of this paper: Pieter 't Hoen (for implementing two of the algorithms from [Wat93b]), and Kees Hemerik, Erik Poll, Nanette Saes, and Gerard Zwaan (for providing style suggestions on this paper).

## 1.1 Coding conventions and performance issues

The toolkit is coded in a style which makes heavy use of the *assert* function. For all except the simplest classes, a member function called *class_invariant* is defined; this member returns 1 if the object is structurally sound, and 0 otherwise. All member functions which are visible to clients should only be invoked on structurally sound objects and must leave the object in a structurally sound condition. The function call *assert( class_invariant() )* is explicitly invoked at the begining and end of all such member functions (except, of course, the function *class_invariant*). The definition of the class invariant is a useful starting point for understanding the structure and implementation of a particular class.

Additional assertions are used in places where the incorrect values of variables (or relations between variables) will cause catastrophic results (i.e. the machine is likely to crash). Assertions are also used in places where they may be of use in understanding the surrounding code. As mentioned below, *assert* can be disabled by compiling with the macro `NDEBUG` defined —meaning that there is no assertion overhead in a production version of the **FIRE engine**.

Almost all of the classes have an *ostream* insertion operator defined (an output operator). For implementation classes the output members are mainly for debugging purposes.

Many classes provide a member function called *reincarnate*. This function clears the object, leaving it in the same condition as it would be in after the argumentless constructor for the object. The only difference is that any memory already allocated by the members of the object is retained for future use.

### 1.1.1 Performance tuning

There are some general techniques that can be used to improve the performance of the various parts of the **FIRE engine** toolkit. The easiest method of improving the performance is to compile the toolkit with the macro `NDEBUG` defined. This will disable the *assert* function call, and should only be done when the program is functioning correctly and the safety of assertions and class invariants is no longer needed. Before hand-optimizing the code itself, an important first step is to profile the execution of the toolkit. Some preliminary profiling shows that a large amount of time is spent copying and allocating memory. Much of this time can be eliminated by using two techniques:

- Define and use special versions of the **new** and **delete** operators for the classes that make extensive use of memory management.
- "Use-count" all classes which copy large amounts of data in their copy constructors or assignment operators. (See any of [Cop92, MeS92, Mur93] for explanations of "use-counting".)

## 1.2 Presentation conventions

Each class is presented in a standard format. The following items appear in the description of a class:

1. The name of the class, and whether it is a user level class (a class intended for use by program components internal and external to the **FIRE engine**), or an implementation level class (one used only by other classes within the **FIRE engine**).
2. The **Files** clause lists the files in which the class declaration and definition are stored. The names of the files accociated with a class are usually the class name, followed by .h for interface (or header) files and .cpp for definition files. All file names are short enough for use under MS-DOS.
3. The **Uses** clause lists the classes of which this class is an immediate client or from which this class inherits directly. (Most classes use themselves; this is not mentioned.)
4. The **Description** clause gives a brief description of the purpose of the class.
5. The .h file (if there is one) corresponding to the class is listed.
6. The optional **Implementation** clause outlines the implementation of the class.
7. The optional **Performance** clause gives some suggestions on possible performance improvements to the implementation of the class.
8. The .cpp file (if there is one) corresponding to the class is listed.
9. The description ends with the □ symbol.

# Part I
# Foundation classes

## 2 Character ranges

The header file `extras.h` contains inline functions for computing minima and maxima of two numbers. The functions are overloaded to provide versions for types **char** and **int**.

---

```
/* (c) Copyright 1994 by Bruce W. Watson */
// $Revision: 1.1 $
// $Date: 1994/05/02 15:58:01 $
#ifndef EXTRAS_H
#define EXTRAS_H

inline int min( const int a, const int b ) {
        return( a < b ? a : b );
}

inline int max( const int a, const int b ) {
        return( a < b ? b : a );
}

#endif
```

---

**User class:** *CharRange*

**Files:** `charrang.h`, `charrang.cpp`

**Uses:**

**Description:** Sets of characters (denoted by a *CharRange*) can be used as automata transition labels and as regular expression atoms (unlike most other systems, which use single characters). The sets of characters are limited to a range of characters in the execution character set (no particular character set is assumed, and ASCII or EBCDIC can both be used). The ranges are specified by their upper and lower (inclusive) bounds. The denoted range may not be empty (allowing them to be empty greatly complicates the algorithms). Many member functions are provided, including functions determining if two *CharRanges* have a character in common, if one is entirely contained in another, or if they denote sets that are adjacent to one another (in the execution character set).

        // signed or unsigned.
        return( lo <= hi );
}                                                                                    180

#endif
```

---

**Implementation:** *CharRanges* are represented as a pair of characters: the upper and lower (inclusive) bounds. There is a potential for problems caused by the fact that the language standard does not specify whether **char** is **signed** or **unsigned**.

**Performance:** In most functions that take a *CharRange*, the parameter passing is by value (since a pair of characters fit into the parameter passing registers on most processors). On some machines, performance can be improved by passing a **const** reference.

---

        }
}
```

---

□

**Implementation class:** *CRSet*

**Files:** `crset.h`, `crset.cpp`

**Uses:** *CharRange*

**Description:** A *CRSet* is a set of *CharRanges*, with a restriction: all *CharRanges* in a *CRSet* are pairwise disjoint. When a new *CharRange* is added to a *CRSet*, some *CharRanges* may be split to ensure that the disjointness property is preserved. Members are provided to check if two *CRSets* cover the same characters, and to combine two *CRSets*.

#endif
```

---

**Implementation:** A *CRSet* contains a pointer to a dynamically allocated array of *CharRanges*, an integer representing the size of the array, and an integer representing the number of elements in the array that are in use. The member *add_at* is a good candidate for optimization.

□

# 3 Bit vectors

**Implementation class:** *BitVec*

**Files:** `bitvec.h`, `bitvec.cpp`

**Uses:** `extras.h`

**Description:** Bit vectors wider than a single word are used in implementing sets without a compiled-in size bound. In addition to many of the standard bit level operators, iterators are also provided. The vectors have a width that is adjustable through a member function. Binary operators on vectors must have operands of the same width, and such width management is left to the client. When a vector is widened, the newly allocated bits are assumed to be zero.

                                                                              210
inline int BitVec::class_invariant() const {
        return( (width() <= words * bits_per_word)
                && (width() >= 0)
                && (words >= 0)
                && (words == 0 ? data == 0 : data != 0) );
}

#endif
```

---

**Implementation:** The implementation is largely replaceable by any standard library providing the same functionality. The width is stored as an integer in the object, along with the number of words allocated. The vector itself is stored as a pointer to an allocated block of **unsigned int**. The width can only grow (except in the case of a *reincarnate* member function call; it will then shrink to zero).

**Performance:** The low level bit operations could benefit from being written in assembler. The copying of the data area that occurs in the copy constructor and assignment operator can be avoided by use-counting. The left shift operator and the iteration operators could be implemented more efficiently.

# 4 States and related classes

**Implementation class:** *State*

**Files:** `state.h`

**Uses:**

**Description:** In the **FIRE engine**, all finite automaton states are encoded as non-negative integers. The special value *Invalid* is used to flag an invalid state.

**Implementation:** Not making *State* a class has the effect that no extra information can be stored in a state, and a *State* can be silently converted to an **int**.

---

```
/* (c) Copyright 1994 by Bruce W. Watson */
// $Revision: 1.1 $
// $Date: 1994/05/02 15:59:44 $
#ifndef STATE_H
#define STATE_H

// Encode automata states as integers.
typedef signed int State;
// Invalid states mean something bad is about to happen.
const State Invalid = -1;                                                    10

#endif
```

---

□

**Implementation class:** *StatePool*

**Files:** `st-pool.h`

**Uses:** *State*

**Description:** A *StatePool* is a dispenser of *States* (beginning with 0). A member function *size()* returns the number of *States* allocated so far. Two *StatePools* can be combined into one, with the result that the *StatePool* being combined into ***this** must be renamed to not clash with the *States* already allocated from ***this**.

**Implementation:** An integer counter is maintained, indicating the next *State* to be allocated. The class is really too simple to have a class invariant.

## Implementation class: *StateSet*

**Files:** `stateset.h`, `stateset.cpp`

**Uses:** *BitVec, State*

**Description:** A *StateSet* is a set of *States* with a certain capacity. The capacity (called the *domain*) is one more than the greatest *State* that the set can contain. It can easily be enlarged, but it can only be shrunk (to zero) through the *reincarnate* member function. The maintainance of the domain is the responsibility of the client. Normal set operations are available, including iterators. Most member functions taking another *StateSet* expect it to have the same *domain* as ***this** (with catastrophic results if this is not true). The *States* in the set can also be renamed, so that they do not clash with the *States* of a certain *StatePool*. It is possible to take the union of two *StateSets* containing *States* from different *StatePools*. In this case, the *States* in the incoming *StateSet* are renamed during the union; this is done with the *disjointing_union* member function.

□

**Implementation class:** *StateTo*

**Files:** `stateto.h`

**Uses:** *State*

**Description:** *StateTo* is a template class implementing mappings from *States* to some class *T* (the template type parameter). It is used extensively in transition relations and binary relations on states. Two methods of mapping a *State* are provided:

- Member function *map* takes a *State* and returns a non-**const** reference to the associated *T*. This is most often used to set up the map, by changing the associated *T*.
- Member function *lookup* takes a *State* and returns a **const** reference to the associated *T*. This is intended for use in clients that only lookup information, without changing the map.

*StateTo* includes a *reincarnate* member function, which does not reincarnate the *T's*. As with *StateSets*, the domain of the *StateTo* must be explicitly maintained by the client. A special member function *disjointing_union* is available which performs a normal union after the domain of the incoming *StateTo* has been renamed to avoid clashing with the domain of ***this**.

**Implementation:** Each *StateTo* contains a pointer to a dynamically allocated array of *T*, an integer indicating the size of the array, and an integer indicating how many of the array elements are in use. Whenever the array of *T* is enlarged, a bit extra is allocated to avoid repeated calls to **new**. Class *T* must have a default constructor, an assignment operator and an insertion (output) operator.

**Performance:** *StateTo* would benefit from use-counting in the class *T*. Use-counting in *StateTo* itself would likely add too much overhead if it were already done in *T*.

# 5 Transitions and related classes

**Implementation class:** *TransPair*

**Files:** `tr-pair.h`

**Uses:** *CharRange, State*

**Description:** A *TransPair* is a transition, a structure consisting of a label (a *CharRange*) and a destination *State*. The two are contained in the *TransPair* structure.

**Implementation:** A **struct** is defined, without member functions.

---

```
/* (c) Copyright 1994 by Bruce W. Watson */
// $Revision: 1.1 $
// $Date: 1994/05/02 16:00:40 $
#ifndef TR_PAIRS_H
#define TR_PAIRS_H
#include "charrang.h"
#include "state.h"

// Implement a single transition, for use in classes TransImpl, Trans (trans.h
// and trans.cpp) and class DTrans (dtrans.h and dtrans.cpp).                    10

struct TransPair {
        CharRange transition_label;
        State transition_destination;
};

#endif
```

---

□

**Implementation class:** *TransImpl*

**Files:** `tr-impl.h`, `tr-impl.cpp`

**Uses:** *CharRange, CRSet, State, StateSet, TransPair*

**Description:** A *TransImpl* is a set of *TransPairs*. It is used as a base class for *Trans* and *DTrans*, which are used to implement transition relations. *TransPairs* can be added, but not removed from the set. When a new *TransPair* is added, if its *CharRange* is adjacent to the *CharRange* of a *TransPair* already in the set, and the destination *State* of the two *TransPairs* is the same, then the two *TransPairs* are merged into one.

};

// Some inline members:
```

```
// Assume that delete [] 0 is okay.
inline TransImpl::TransImpl() :
                howmany( 0 ),
                in_use( 0 ),
                data( 0 ) {                                              90
        assert( class_invariant() );
}

inline void TransImpl::reincarnate() {
        assert( class_invariant() );
        in_use = 0;
        assert( class_invariant() );
}

inline TransPair& TransImpl::transitions( const int i ) const {          100
        assert( class_invariant() );
        // i can be greater than in_use in some weird cases where the
        // transitions are still being set up.
        assert( 0 <= i );
        return( data[i] );
}

// Maintain the class invariant.
inline int TransImpl::class_invariant() const {
        auto int ret( 1 );                                               110
        auto int i;
        for( i = 0; (i < in_use) && ret; i++ ) {
                ret = (data[i].transition_destination >= 0);
        }
        ret = ret && (in_use <= howmany);
        return( ret );
}

#endif
                                                                         120
```

---

**Implementation:** A *TransImpl* contains a pointer to a dynamically allocated array of *TransPair*, an integer indicating the size of the array, and an integer indicating how much of the array is in use.

**Performance:** Use-counting this class would bring a great benefit to *Trans*, *DTrans*, *TransRel*, and *DTransRel*.

□

**Implementation class:** *Trans*

**Files:** `trans.h`, `trans.cpp`

**Uses:** *CharRange, CRSet, State, StateSet, TransImpl, TransPair*

**Description:** A *Trans* is a set of *TransPairs* (transitions) for use in transition relations. Transitions can be added to the set, but not removed. Member functions are provided to compute the destination of the transition set, on a particular character or on a *CharRange* (the destination is returned as a *StateSet*). Since a *StateSet* is returned, *Trans* has a range (which is one more than the maximum *State* that can occur as a transition destination) which is managed by the client and is used to determine the domain of the returned *StateSet*. Another member function computes the set of all transition labels, returning a *CRSet*.

□

**Implementation class:** *DTrans*

**Files:** `dtrans.h`, `dtrans.cpp`

**Uses:** *CharRange, CRSet, State, StateSet, TransImpl, TransPair*

**Description:** A *DTrans* is a set of *TransPairs*, with one restriction: the transition labels (*CharRanges*) are pairwise disjoint. (They are pairwise disjoint, since *DTrans* is used to implement deterministic transition functions.) The client must ensure that only transitions with disjoint labels are added. Member functions are provided to compute the destination of a transition, on a particular character or *CharRange*, returning a *State* (which is *Invalid* if there is no applicable transition). A *State* is returned (instead of a *StateSet*), since *DTrans* implement deterministic transition sets. A member function computes the set of all transition labels,

returning a *CRSet*. Another member takes a *StateSet* and returns the set of all transition labels on transitions with the destination in the *StateSet*.

□

# 6 Relations

**Implementation class:** *StateRel*

**Files:** `staterel.h`, `staterel.cpp`

**Uses:** *State, StateSet, StateTo*

**Description:** A *StateRel* is a binary relation on *States*. The class is used in the implementation of the $\epsilon$-transition relation for class *FA* [Wat93a, Definition 2.1] and the *follow* relation [Wat93a, Definition 4.24] in classes *RFA, LBFA* and *RBFA*. Many relation operators are available, including taking the image of a *State* or a *StateSet*, and the star-closure of a *StateSet*. In order to easily construct *StateRels*, a member function *union_cross* is provided, which performs the following operation (where $l, r$ are either *States* or *StateSets*):

$$*\textbf{this} := *\textbf{this} \cup (l \times r)$$

Standard union is available, as is *disjointing_union* which operates analogously to the member function in *StateSet* and *StateTo* (incoming *States* are renamed to avoid a collision). As with *StateSet*, the domain must be explicitly maintained by the client. Those member functions which take a *StateSet* or *StateRel* as parameter expect the parameter to have the same domain as ***this**.

□

**Implementation class:** *StateEqRel*

**Files:** `st-eqrel.h`, `st-eqrel.cpp`

**Uses:** *State, StateSet, StateTo*

**Description:** A *StateEqRel* is a binary equivalence relation on *States*. They are used mainly in *DFA* minimization algorithms. The argumentless constructor leaves the *StateEqRel* as the total relation. The *identity* member function makes the *StateEqRel* the identity relation. As with many other classes related to sets of *States*, the domain of the *StateEqRel* must be managed by the client. Member functions are available for determining if two *States* are equivalent, for splitting an equivalence class, and for determining the equivalence class (as a *StateSet*) of a *State*. Each equivalence class has a unique representative; if an equivalence class is split, one of the (at most two) resulting classes is guaranteed to have, as its unique

representative, the representative of the original class. Iterator member functions can be used to iterate over the set of representatives, thereby iterating over the set of equivalence classes.

**Implementation class:** *TransRel*

**Files:** `transrel.h`, `transrel.cpp`

**Uses:** *CharRange, CRSet, State, StateSet, StateTo, Trans*

**Description:** A *TransRel* maps a *StateSet* and a character (or a *CharRange*) to a *StateSet*. It is used to implement the transition relation in the class *FA* (see [Wat93a, Definition 2.1]). The responsibility of maintaining the domain of the relation lies with the client. Transitions can be added, but not removed.

□

**Implementation class:** *DTransRel*

**Files:** `dtransre.h`, `dtransre.cpp`

**Uses:** *CharRange, CRSet, DTrans, State, StateSet, StateTo*

**Description:** A *DTransRel* maps a *State* and a character (or a *CharRange*) to a *State*. It is used to implement the deterministic transition relation in the class *DFA* (see [Wat93a, Property 2.25]). The domain of the relation must be maintained explicitly by the client. Transitions can be added to the relation, but not removed. The client must ensure that the relation remains deterministic.

# Part II
# Regular expressions and Σ-algebras

## 7 Regular expressions

**Implementation class:** *REops*

**Files:** `reops.h`

**Uses:**

**Description:** The regular operators (of the Σ-algebra — see class *Reg* or [Wat93a, Definition 3.12]) are encoded as elements of an enumeration. These are usually stored in a type-field in regular expressions. They play an important role in computing the homomorphic (Σ-algebra) image of a regular expression.

**Implementation:** *REops* is defined as an **enum**.

---

```

// $Revision: 1.1 $
// $Date: 1994/05/02 15:59:25 $
#ifndef REOPS_H
#define REOPS_H

// Define the regular operators as an enumerated type. These correspond to the
// Sigma algebra operators (see Definition 3.12 of the Taxonomy, and Sigma.h).
                                                                          10
enum REops {
        EPSILON,
        EMPTY,
        SYMBOL,
        OR,
        CONCAT,
        STAR,
        PLUS,
        QUESTION
};                                                                        20

#endif
```

---

□

**Implementation class:** *RE*

**Files:** `re.h`, `re.cpp`

**Uses:** *CharRange, CRSet, REops*

**Description:** An *RE* is a regular expression (see [Wat93a, Section 3] for the definition of regular expressions). The argumentless constructor constructs the regular expression ∅ (the regular expression denoting the empty language). It is not possible to construct more complex regular expressions with the member functions (see the template class *Reg*<*RE*> for information on constructing regular expressions). Class *RE* is the implementation of the carrier set of the Σ-term algebra (an *RE* is a term in the Σ-term algebra).

A member function returns the operator type of the main (or root) operator of the regular expression. (The operator types are enumerated in *REops*.) Other member functions can be used to determine additional information about the main (root) operator of the regular

expression: the associated *CharRange* (for a *SYMBOL* basis operator), and the subexpressions (for non-basis, binary and unary, operators). A very basic *istream* extraction (input) operator is provided, expecting the input to be a regular expression in prefix notation; the operator does little error checking.

        case STAR:
        case PLUS:
```

```
        case QUESTION:
                return( left != 0 && right == 0
                        && left_subexpr().class_invariant() );
        default:
                return( 0 );                                                    200
        }
}

#endif
```

---

**Implementation:** Regular expressions are implemented as expression trees. The comparison of regular expressions is defined recursively and uses a depth-first traversal.

**Performance:** Use-counting could avoid the deep-tree copies that are performed. An *RE* could be stored as a prefix-form string, as in [RW93]; this could give some problems with the heavy use of members such as *left_subexpr* and *right_subexpr*.

## 7.1 Similarity of *REs*

Similarity is an equivalence relation on regular expressions, defined in [Wat93a, Definition 5.26]. A pair of similar regular expressions denote the same language, while their expression trees may not be identical. Similarity is used extensively in Brzozowski's deterministic finite automata construction [Wat93a, Construction 5.34].

The normal *RE* equality operator can be used to determine the similarity of two regular expressions if they are both in similarity normal form (SNF). In order to put an *RE* into SNF, we define a total ordering (which we will also write as $\leq$) on regular expressions; the member function *ordering* takes two regular expressions and returns a negative integer, zero, or a positive integer depending upon their relative position in the total ordering. (The ordering is essentially the lexicographic ordering of the prefix-form of the regular expression.) An *RE* is in SNF if and only if all of its subexpressions are in SNF, and all *OR* subexpressions (subexpressions with *OR* as the root operator[1]) are in *OR* normal form (ONF). An *OR* regular expression is in ONF if and only if:

[1] operator *OR* corresponds to the $\cup$ operator in [Wat93a, Section 3], and we sometimes write $\cup$ instead of *OR*

- All of its *OR* operators are left-associative; for example $(E_0 \cup E_1) \cup E_2$ is left-associative, while $E_0 \cup (E_1 \cup E_2)$ is not.
- The *OR* regular expression is in one of two forms (where $\leq$ is the total ordering on regular expressions): either $(E_0 \cup E_1) \cup E_2$ where $E_1 < E_2$ and $(E_0 \cup E_1)$ is in ONF, or $E_0 \cup E_1$ where $E_0 < E_1$. (The use of $<$ instead of $\leq$ implies that if the subexpressions of an *OR* expression are equal (under the total ordering), then they are collapsed into one expression, implementing the idempotence of *OR*.)

The ONF is used to provide the equivalent of a multi-ary *OR* operator, implementing the associativity, commutativity and idempotence of the *OR* operator, as detailed in [Wat93a, Definition 5.26].

The member function *in_snf* returns 1 if the *RE* is in SNF, and 0 otherwise. The member *snf* puts the *RE* in SNF, using function *onf* as a helper. Member function *reduce* optimizes an *RE*, removing any redundant subexpressions. It implements rules 1 to 5 of [Wat93a, Remark 5.32]. The function performs a bottom-up traversal of the regular expression, making such transformations as $\emptyset \cdot E \longrightarrow \emptyset$ and $\emptyset^* \longrightarrow \epsilon$.

All of these members (including the total ordering) are defined in file `deriv.cpp`.

## 7.2 Derivatives

Two functions on regular expressions, *Null* and *First* (see [Wat93a, Example 3.20, Definition 4.60] — both used in computing derivatives of regular expressions), are defined as recursive member functions in file `deriv.cpp`. Function *Null* returns 1 if the empty word ($\epsilon$) is in the language denoted by the regular expression, and 0 otherwise. Function *First* returns a *CRSet* denoting the characters which can occur as the first character of a word in the language denoted by the regular expression.

Member function *derivative* takes a *CharRange* and returns the derivative of the regular expression with respect to the *CharRange*. The derivative is computed recursively according to the definition given in [Wat93a, Definition 5.23]. It is used in the implementation of Brzozowski's construction.

# 8 The Σ-algebra

The Σ-algebra (as defined in [Wat93a, Section 3]) is defined as a template class.

**Implementation class:** *Reg*

**Files:** `sigma.h`

**Uses:** *CharRange, RE, REops*

**Description:** *Reg* implements the Σ-algebra as defined in [Wat93a, Section 3]. The single type (or generic) parameter *T* is used to specify the carrier set of the Σ-algebra. The template *Reg* is an abstract template, in the sense that it is only used to force a common interface between the Σ-algebras. Most of the member functions are left undefined, with versions specific to the carrier set being defined separately (see files `sig-re.cpp`, `sig-fa.cpp`, and `sig-rfa.cpp`). Regular expressions (class *RE*) are taken as the Σ-term algebra. A special member function is defined, taking a regular expression, and constructing the homomorphic image of the *RE*, in the Σ-algebra of *T*. The Σ-algebra is the only way to construct regular expressions, and it is particularly useful for constructing parts of a finite automaton separately. *Reg*<*T*> inherits publicly from a *T*, and since a *Reg*<*T*> contains nothing extra, it can be cast to a *T* safely (no slicing occurs, and no information is lost). Presently, only *Reg*<*RE*>, *Reg*<*FA*>, and *Reg*<*RFA*> are available. (Each of *RE*, *FA*, and *RFA* also have constructors taking a **const** reference to *RE*; for practical purposes, these constructors are much faster than constructing the homomorphic image using *Reg*.)

**Implementation:** The template is used to force a common interface for Σ-algebras with different carrier sets. Forcing an interface is commonly done using abstract base classes, although this is not possible in this case, as the return types of many of the member functions would not be correct.

**Performance:** The homomorphic image member function is recursive, and keeps partially constructed results in local variables. Use-counting in the carrier class can improve performance.

## 8.1 The Σ-term algebra *Reg<RE>*

**Implementation class:** *Reg<RE>*

**Files:** `sig-re.cpp`

**Uses:** *CharRange, Reg, RE, REops*

**Description:** The template instantiation *Reg<RE>* can be used to construct regular expressions (see the documentation on template class *Reg*).

**Implementation:** The implementation consists of straight-forward expression tree manipulations. The implementation of *RE* is declared **protected** to give *Reg<RE>* access to it.

**Performance:** These member functions would benefit from use-counting of class *RE*.

# Part III
# Automata and their components

## 9 Abstract finite automata

**Implementation class:** *FAabs*

**Files:** `faabs.h`

**Uses:** *DFA* (mentioned)

**Description:** *FAabs* is an abstract class, used to provide a common interface to the different types of finite automata (which are *FA*, *DFA*, *RFA*, *LBFA*, and *RBFA*). The following operations are provided via member functions:

1. determine how many states there are in the concrete finite automaton;
2. restart the finite automaton in its start states;
3. advance to a new set of states (make a transition) on a character;
4. determine if the automaton is in accepting states;
5. determine if the automaton is stuck (unable to make further transitions);
6. determine if a string is in the language of the automaton, and
7. return a deterministic finite automaton (a *DFA*) which accepts the same language.

By convention, the argumentless constructor of a class inheriting from *FAabs* must construct an object of that class that accepts the empty language (i.e. the object does not accept anything).

**Implementation:** Since it is an abstract base class (pure virtual), all except one of the member functions are pure virtual; the *acceptable* member function is defined.

---

```

#ifndef FAABS_H
#define FAABS_H

// Just mention DFA here, since circularity would be a problem if we include dfa.h.
class DFA;

// Abstract finite automaton. All other automaton types are derived from this one.
// Basic FA operations are supported.

class FAabs {
public:
        // Return the number of states (or some reasonably close measure).
        virtual int num_states() const = 0;

        // Reset the current state before beginning to process a string.
        // This is not the default condition for most of the derived classes.
        virtual void restart() = 0;

        // Advance the current state by processing a character.
        virtual void advance( char a ) = 0;

        // Is the current state an accepting (final) one?
        virtual int in_final() const = 0;

        // Is the automaton stuck?
```

```
        virtual int stuck() = 0;
                                                                              30
        // Is the string w acceptable?
        virtual int acceptable( const char *w ) {
                for( restart(); !stuck() && *w; advance( *(w++) ) ) {}
                // It's acceptable if *this is final, and the whole of w was consumed.
                return( in_final() && !*w );
        }

        // Return a DFA accepting the same language as *this.
        virtual DFA determinism() const = 0;
};                                                                            40

#endif
```

---

□

# 10 Deterministic *FAs*

**Implementation class:** *DFA*

**Files:** `dfa.h`, `dfa.cpp`

**Uses:** *DFA_components, DSDFARev, DTransRel, FAabs, State, StateSet, StateEqRel, SymRel*

**Description:** A *DFA* is a deterministic finite automaton (see [Wat93a, Property 2.25] for the definition of *DFA*). It implements the interface required by the abstract class *FAabs*. Additionally, it also provides member functions to reverse the automaton, and to minimize it (the minimization functions are described later). A special constructor is provided, which takes a structure containing the essential components of a *DFA*, and uses those components to construct the automaton; this constructor is used in several *DFA* constructions involving the subset construction (see [Wat93a, p. 12–13] for the subset construction).

inline DFA& DFA::min_Brzozowski() {
        assert( class_invariant() );
        return( reverse().reverse() );
}

inline int DFA::class_invariant() const {
        return( Q.size() == S.domain()
                && Q.size() == F.domain()
                && Q.size() == T.domain()
                && current < Q.size()                                        140
                && S.size() <= 1 );
}

#endif
```

---

**Implementation:** All of the member functions are straight-forward implementations, with the exception of the minimization and reversal member functions. Those are further described later (the minimization member functions are discussed in Part IV). The constructor which takes a *DFA_components* object is only provided because most C++ compilers do not support template member functions yet. When these are fully supported, template function *construct_components* will be inlined in the constructor.

**Performance:** Use-counting the classes used in the automata (such as *DTransRel* and *StateSet*) would improve performance on copy construction and assignment.

# 11 Constructing a *DFA*

**Implementation class:** *DFA_components*

**Files:** `dfacomp.h`

**Uses:** *DTransRel, StatePool, StateSet*

**Description:** A *DFA_components* is a structure containing the essential parts of a *DFA*. Class *DFA* has a constructor taking a *DFA_components*. It is used in the subset construction, as the return type of template function *construct_components*.

**Implementation:** The class is implemented as a **struct**.

**Performance:** The template function *construct_components* should really be a constructor template of *DFA*. This would avoid needing *DFA_components*, and the overhead of passing the structure by value.

□

## 11.1 Abstract states and the subset construction

An abstract state is a certain type of object used in the construction of a *DFA*. They are essentially states in the subset construction (see [Wat93a, p. 12–13]) with some extra information. The template function *construct_components* uses the extra information to construct a *DFA*. All abstract states in **FIRE engine** are implemented using classes with names beginning with *DS*, such as *DSDFARev*. An abstract state must have the following member functions:

- an argumentless constructor, a copy constructor, an assignment operator, and equality and inequality operators;
- *final* — returns 1 if the abstract state is an accepting (final) state, 0 otherwise;
- *out_labels* — returns a *CRSet* representing the set of labels of out-transitions from the abstract state; and
- *out_transition* — takes a *CharRange* (which is an element of the *CRSet* returned by *out_labels*), and returns the abstract state resulting from a transition on the *CharRange*.

**Implementation function:** *construct_components*

**Files:** `dfaseed.h`

**Uses:** *CharRange, CRSet, DFA_components, State, StateTo*

**Description:** Template function *construct_components* implements the subset construction, with useless state removal [Wat93a, p. 12–13]. It takes an "abstract state" and constructs the components of a *DFA* (using the abstract state argument as the start state), returning them in a *DFA_components* structure. It does this by encoding the abstract states as *States*, using a breadth-first traversal of the start-reachable abstract states. During the traversal, the deterministic transition relation (a *DTransRel*) is also constructed. As a result of using a traversal starting at the start state, only reachable *States* and the reachable part of the deterministic transition relation are constructed.

**Implementation:** This template function should really appear as a template constructor of class *DFA*. It is implemented separately, as template member functions have only recently been incorporated into the draft of the C++ language standard. The function implements the subset construction (see [Wat93a, pp. 12, 13]). Each abstract state is assigned a *State*, using a *StateTo* to keep track of the names assigned. The out-transitions from each *State* are constructed, using the *StateTo* to lookup the encoding of an abstract state. The abstract state classes are to be written in such a way that there are only finitely many of them, thereby ensuring termination of the function. The useless state removal is hidden in the fact that, by starting with the start state, only reachable *States* are constructed.

**Performance:** The performance could be greatly increased by making this template function a template constructor of class *DFA*, avoiding by-value structure passing.

                        assert( dest == names.lookup( i ) );
                        // Create the actual transition.
                        ret.T.add_transition( current, b, i );
                }
                // That's all for current.
        }

        // Time to resynchronize the domain() of ret.S with ret.Q.size():      90
        ret.S.set_domain( ret.Q.size() );
        // Add the start State now.
        ret.S.add( s );

        // Return, constructing the DFA on the way out.
        return( ret );
}

#endif                                                                         100
```

□

As an example of an abstract state, consider class *DSDFARev*.

**Implementation class:** *DSDFARev*

**Files:** `dsdfarev.h`, `dsdfarev.cpp`

**Uses:** *CharRange, CRSet, DTransRel, StateSet*

**Description:** Class *DSDFARev* is used in the reversal of a *DFA*. It is an abstract state representing a set of states, in the reversal of the deterministic automaton (the reversal of a deterministic finite automaton is not necessarily deterministic). A *DSDFARev* is constructed in the *DFA* member function *reverse*. Member functions support all of the required interface of an abstract state.

## 11.2 Derivatives of regular expressions

**Implementation class:** *DSRE*

**Files:** `dsre.h`, `dsre.cpp`

**Uses:** *CharRange, CRSet, RE*

**Description:** A *DSRE* represents a derivative of a regular expression. A derivative of a regular expression is again a regular expression; a *DSRE* simply provides an abstract state interface to the derivatives.

```
/* (c) Copyright 1994 by Bruce W. Watson */
// $Revision: 1.1 $
// $Date: 1994/05/02 15:57:44 $
#ifndef DSRE_H
#define DSRE_H

#include "charrang.h"
#include "crset.h"
#include "re.h"
#include <assert.h>
#include <iostream.h>

// This class is used to represent abstract States in a DFA that is still under
// construction. It is used in the construction of a DFA from an RE (using
// Brzozowski's construction). Most member functions are calls through to the
```

```
// corresponding RE members.
// DSRE inherits from RE for implementation.

class DSRE : protected RE {                                              20
public:
        // Must always have an argument-less constructor.

        inline int class_invariant() const;                              40
};

// Must always have an argument-less constructor.
inline DSRE::DSRE() :
                RE() {
        assert( class_invariant() );
}

inline DSRE::DSRE( const RE& r ) :
                RE( r ) {                                                50
        assert( r.class_invariant() );
        // They must always be in similarity normal form SNF (see deriv.cpp)
        RE::snf();
        assert( class_invariant() );
}

inline const DSRE& DSRE::operator=( const DSRE& r ) {
        assert( r.class_invariant() );
        RE::operator=( (const RE&)r );
        assert( class_invariant() );                                     60
        return( *this );
}

inline int DSRE::final() const {
        assert( class_invariant() );
        return( RE::Null() );
}

inline CRSet DSRE::out_labels() const {
        assert( class_invariant() );                                     70
        return( RE::First() );
}

inline DSRE DSRE::out_transition( const CharRange a ) const {
        assert( class_invariant() );
        return( RE::derivative( a ) );
}

inline int DSRE::operator==( const DSRE& r ) const {
        assert( class_invariant() );                                     80
        assert( r.class_invariant() );
        return( RE::operator==( r ) );
}
```

```
inline int DSRE::operator!=( const DSRE& r ) const {
        return( !operator==( r ) );
}

inline int DSRE::class_invariant() const {
        return( RE::class_invariant() && RE::in_snf() );                    90
}

#endif
```

---

**Implementation:** A *DSRE* inherits from *RE*. The interface required of abstract states (such as member functions *final*, *out_labels*, and *out_transition*) is provided through the use of the *RE* member functions such as *Null*, *First*, and *derivative* (respectively). When a new *DSRE* is constructed, it is put into similarity normal form, to ensure that there will only be finitely many *DSREs* (see [Wat93a, Theorem 5.31]).

**Performance:** *RE* member function *derivative* returns an *RE* by value, which is then passed to the *DSRE* constructor. Use-counting *RE* could eliminate the overhead of copy constructor and destructor calls.

---

```

        return( os << "\nDSRE\n" << (const RE&)r );
}
                                                                    10
```

---

□

**Implementation class:** *DSREopt*

**Files:** `dsre-opt.h`, `dsre-opt.cpp`

**Uses:** *CharRange, CRSet, RE*

**Description:** This class is identical to *DSRE*, with one addition: the underlying regular expression (the derivative) is reduced — redundant subexpressions are eliminated. This makes it more likely that two derivatives (denoting the same language) will be found to be equal (using the *DSREopt* equality operator) in template function *construct_components*, thus giving a *DFA* with fewer *States*.

□

## 11.3 Item sets

**Implementation class:** *ISImpl*

**Files:** `is-impl.h`, `is-impl.cpp`

**Uses:** *BitVec, CharRange, CRSet, RE*

**Description:** *ISImpl* is a base class implementing an item set [Wat93a, Definition 5.58]. It is used as a base class in abstract state classes *DSIS*, *DSDeRemer*, and *DSIS_opt*. It includes a constructor from a pointer to *RE* (the regular expression associated with the item set). The pointed-to *RE* is assumed to remain in existence while the *DFA* components are constructed by template function *construct_components*. Additionally, the abstract state members *final* and *out_labels* are defined. The member function *move_dots* takes a *CharRange* and provides the functionality of "derivatives of item sets" (as defined in [Wat93a, Definition 5.61]), while member function $D$ implements the dot closure relation $\mathcal{D}$ defined in [Wat93a, Definition 5.63].

}

#endif
```

**Implementation:** As explained in [Wat93a, Section 5.5], a dot (an item in an item set) can occur either before or after a regular expression, or any of its subexpressions. The subexpressions of the associated regular expression (including the expression itself) are encoded by their node number (starting at 0) in a prefix traversal of the *RE* expression tree. The dots before subexpressions are stored as bits in a *BitVec* called *before*, while the dots after subexpressions are store as bits in a *BitVec*, called *after* (in both cases, the bits indicate if the corresponding dot is present). Two *ISImpls* are equal if these two *BitVecs* are equal, i.e. their dots before and after are equal. The member functions *move_dots* and *D* both make prefix traversals of the *RE* expression tree, keeping track of the prefix number of each subexpression.

}

#endif
```

---

**Implementation:** The implementation is largely provided by the base class *ISImpl*. The member function *opt* (with helper *traverse_opt*) implements DeRemer's dot filter function $\mathcal{X}$ as defined in [Wat93a, Definition 5.72]. The filter function makes a single prefix traversal of the *RE* expression tree. By applying the filter, it becomes more likely that template function *construct_components* will find two item sets (denoting the same language) to be equal (this will result in fewer states in the constructed *DFA*).

# 12 Finite automata

**Implementation class:** *FA*

**Files:** `fa.h`, `fa.cpp`

**Uses:** *FAabs, RE, State, StatePool, StateRel, StateSet, TransRel*

**Description:** Class *FA* implements finite automata as defined in [Wat93a, Definition 2.1]. It inherits from *FAabs*, and implements the interface defined there. A constructor taking an *RE* is provided, implementing Thompson's top-down construction [Wat93a, Construction 4.5]. This constructor can be more efficient than using the Σ-algebra *Reg<FA>*.

---

```

#define FA_H

#include "faabs.h"
#include "st-pool.h"
#include "stateset.h"
#include "staterel.h"
#include "transrel.h"
#include "re.h"
#include <assert.h>
#include <iostream.h>

// Implement general finite automata (Definition 2.1 of the Taxonomy).
// These can be constructed by the Sigma-algebra (see sig-fa.cpp) or using
// the special constructor from RE's.

class FA : virtual public FAabs {
public:
        // Constructors, destructors, operator=:
        FA();

        // Provide a copy constructor:
        FA( const FA& r );

        // A special constructor, implementing the Thompson's top-down construction
        // (see Construction 4.5).
        FA( const RE& e );

        // Default operator= is okay.

        // Basic FAabs member functions (without overriding acceptable()):

        virtual int num_states() const;
        virtual void restart();
        virtual void advance( char a );
        virtual int in_final() const;
        virtual int stuck();
        virtual DFA determinism() const;

        // Special member functions:

        friend ostream& operator<<( ostream& os, const FA& r );

        inline int class_invariant() const;

protected:
        // Functions states_reqd, td (see Construction 4.5) for use in the constructor from RE.
        int states_reqd( const RE& e );
        void td( const State s, const RE& e, const State f );
```

```
        // recycle this FA:
        void reincarnate();

        // Implementation details:

        StatePool Q;                                                    60
        StateSet S, F;

        // Transitions maps each State to its out-transitions.
        TransRel Transitions;
        // E is the epsilon transition relation.
        StateRel E;

        // Simulation stuff:
        StateSet current;
};                                                                      70

inline int FA::class_invariant() const {
        // Should also check that current is E-closed.
        return( Q.size() == S.domain()
                && Q.size() == F.domain()
                && Q.size() == Transitions.domain()
                && Q.size() == E.domain()
                && Q.size() == current.domain()
                && S.class_invariant()
                && F.class_invariant()                                  80
                && Transitions.class_invariant()
                && E.class_invariant()
                && current.class_invariant() );
}

#endif
```

---

**Implementation:** Most of the member functions are implemented in a straight-forward manner. The constructor from an *RE* makes a traversal of the *RE* to determine the number of *States* to allocate before-hand.

**Performance:** Since Thompson's construction yields finite automata with certain structural properties (see [Wat93a, end of Definition 4.1]), a special "Thompson's construction" automata class could be efficiently implemented, instead of the general finite automaton structure defined in *FA*.

## 12.1 The Σ-algebra *Reg<FA>*

**Implementation class:** *Reg<FA>*

**Files:** `sig-fa.cpp`

**Uses:** *CharRange, FA, Reg, State*

**Description:** The template instantiation *Reg<FA>* implements Thompson's Σ-algebra of finite automata, as defined in [Wat93a, Definition 4.1]. The operators can be used directly to construct complex finite automata, or the *Reg<FA>* constructor from *RE* (the constructor defined in class *Reg*) can be used to construct the homomorphic image of the regular expression (the constructor uses these operators indirectly).

**Implementation:** The implementation follows directly from [Wat93a, Definition 4.1]. In some places it is complicated by the management of domains of *StateSets*, *StateRels*, and *TransRels*.

# 13 Reduced finite automata

**Implementation class:** *RFA*

**Files:** `rfa.h`, `rfa.cpp`

**Uses:** *DFA, FAabs, LBFA, RBFA, RE, StatePool, StateRel, StateSet, Trans*

**Description:** Class *RFA* implements reduced finite automata, as defined in [Wat93a, Definition 4.24]. It inherits from *FAabs*, and implements the interface defined by abstract base *FAabs*. A constructor taking an *RE* provides a very efficient top-down implementation of homomorphism *rfa* defined in [Wat93a, Definition 4.30].

        StateSet first, last;
        Trans Qmap_inverse;                                                         80
        StateRel follow;
        int Nullable;

        // Some simulation stuff.
        int final;
        StateSet current;
};

inline int RFA::class_invariant() const {
        return( Q.size() == first.domain()                                          90
                && Q.size() == last.domain()
                && Q.size() == Qmap_inverse.range()
                && Q.size() == follow.domain()
                && Q.size() == current.domain()
                && first.class_invariant()
                && last.class_invariant()
                && Qmap_inverse.class_invariant()
                && follow.class_invariant()
                && current.class_invariant() );
}                                                                                   100

#endif
```

---

**Implementation:** Most of the member functions are implemented in a straight-forward manner. In implementing *RFA*, a choice must be made between the two interpretations of *States*: the left-biased or the right-biased interpretation (see the bottom of p. 73 in [Wat93a] for a brief explanation of the different interpretations). The interpretation chosen here is the right-biased one, since it appears to be the most efficient one in practice.

                && which.domain() == last->domain() );
}

#endif
```

---

**Implementation:** A *DSRFA2* contains a *StateSet*, representing the set of *RFA States* that make up a *DFA* state in the subset construction (under the left-biased interpretation of states). It also contains an integer indicating if the abstract state is a final one.

**Performance:** For higher performance in constructing a *DFA*, use class *DSRFA* instead.

## 13.1 The Σ-algebra *Reg<RFA>*

**Implementation class:** *Reg<RFA>*

**Files:** `sig-rfa.cpp`

**Uses:** *CharRange, Reg, RFA*

**Description:** The template instantiation *Reg<RFA>* implements the Σ-algebra of reduced finite automata, as defined in [Wat93a, Definition 4.29]. The operators can be used directly to construct complex *RFAs*, or the *Reg<RFA>* constructor from *RE* (which is defined in template class *Reg*) can be used to construct the homomorphic image of the regular expression.

**Implementation:** The implementation follows directly from [Wat93a, Definition 4.29].

# 14 Left-biased finite automata

**Implementation class:** *LBFA*

**Files:** `lbfa.h`, `lbfa.cpp`

**Uses:** *DFA, FAabs, RFA, State, StatePool, StateRel, StateSet, Trans*

**Description:** Class *LBFA* implements left-biased finite automata, as defined in [Wat93a, Definition 4.20]. It inherits from *FAabs*, and implements the interface defined by abstract base *FAabs*. A constructor taking an *RFA* provides a method of (indirectly) constructing an *LBFA* from regular expressions. The constructor implements isomorphism *decode* as defined in [Wat93a, Definition 4.28]. A special member function takes an an *RFA* and implements the non-isomorphic mapping *convert* defined in [Wat93a, Definition 4.35]. This mapping provides an alternative way of constructing an *LBFA* from an *RFA* (see [Wat93a, p. 36–37]).

# 15 Right-biased finite automata

**Implementation class:** *RBFA*

**Files:** `rbfa.h`, `rbfa.cpp`

**Uses:** *DFA, FAabs, RFA, State, StatePool, StateRel, Trans*

**Description:** Class *RBFA* implements right-biased finite automata, as defined in [Wat93a, Construction 4.43]. It inherits from *FAabs*, and implements the interface defined by abstract base class *FAabs*. A constructor taking an *RFA* provides a method of (indirectly) constructing an *RBFA* from regular expressions. The constructor implements isomorphism $R \circ decode \circ R$ as defined in [Wat93a, p. 41]. A special member function takes a reference to an *RFA* and implements the non-isomorphic mapping $R \circ convert \circ R$ defined in [Wat93a, p. 43]. This mapping provides an alternative way of constructing an *RBFA* from an *RFA* (see [Wat93a, p. 42–43]).

□

**Implementation class:** *DSRBFA*

**Files:** `dsrbfa.h`, `dsrbfa.cpp`

**Uses:** *CharRange, CRSet, StateRel, StateSet, Trans*

**Description:** Class *DSRBFA* implements the abstract class interface required to construct a *DFA* from an *RBFA*. A *DSRBFA* is constructed in the *RBFA* member function *determinism*, and then passed to template function *construct_components*, which constructs the components of the *DFA*.

# 16 Automata constructions

The finite automata construction functions are functions which take an *RE* (or a pointer to an *RE*) and return an automaton of some type (one of *FA*, *RFA*, *LBFA*, *RBFA*, or *DFA*). Functions implementing Brzozowski's construction [Wat93a, Section 5.3] are given in `dconstrs.cpp` and `dconstrs.h`. Functions implementing the item set constructions [Wat93a, Section 5.5] are given in `iconstrs.cpp` and `iconstrs.h`. Files `constrs.h` and `constrs.cpp` contain all of the remaining functions (from [Wat93a, Section 4]).

All of the function declarations (or prototypes) are accompanied by their corresponding reference in [Wat93a].

# Part IV
# Minimizing *DFAs*

An interesting *DFA* minimization function is the one due to Brzozowski (appearing in [Wat93b, Section 2]).

**User function:** *DFA::min_Brzozowski*

**Files:** `dfa.h`

**Uses:** see the entry for class *DFA*

**Description:** Brzozowski's minimization algorithm differs from all of the other minimization algorithms, and appears as inline *DFA* member function *min_Brzozowski*. The member function simply minimizes the *DFA*.

**Implementation:** The implementation appears in file `dfa.h`. The implementation follows directly from [Wat93b, Section 2].

□

The remainder of Part IV deals with the other minimization functions, based upon their derivations in [Wat93b].

# 17 Helper functions

Two member functions of class *DFA* are used as helpers in those minimization functions which are based upon an equivalence relation (see [Wat93b, Section 3]).

**Implementation function:** *DFA::compress*

**Files:** `dfa.cpp`

**Uses:** see the entry for class *DFA*

**Description:** Member function *compress* is overloaded to take either a *StateEqRel* (an equivalence relation on *States*), or a *SymRel* (a symmetrical relation on *States*). The relation is assumed to be a refinement of relation $E$ [Wat93b, Definition 3.3]. The member function implements function *merge* defined in [Wat93b, Transformation 3.1].

**Implementation:** The implementation appears in file `dfa.cpp`. The implementation follows directly from [Wat93b, Transformation 3.1].

□

**Implementation function:** *DFA::split*

**Files:** `min.cpp`

**Uses:** *CharRange, DFA, State, StateEqRel, StateSet*

**Description:** Member function *split* takes two *States* ($p$ and $q$), a *CharRange* $a$, and a *StateEqRel*. The two *States* are assumed to be representatives in the *StateEqRel*. The equivalence class of $p$ is then split into those *States* (equivalent to $p$) which transition on $a$ to a *State* equivalent to $q$, and those that do not. If in fact there was a split (the equivalence class of $p$ is split into two equivalence classes), $p$ will still be the unique representative of one of the two new equivalence classes; in this case, the (unique) representative of the other equivalence class is returned. If no such split occurred, function *split* returns *Invalid*.

**Implementation:** The implementation is a simple, iterative one. It implements the equivalent of the assignment to $Q'_0$ in Algorithm 4.4 of [Wat93b].

□

# 18 Aho, Sethi, and Ullman's algorithm

**User function:** *DFA::min_dragon*

**Files:** `min-asu.cpp`

**Uses:** *CRSet, DFA, State, StateEqRel, StateSet*

**Description:** Member function *min_dragon* is an implementation of Algorithm 4.6 in [Wat93b]. It is named the "dragon" function after Aho, Sethi, and Ullman's "dragon book" [ASU86].

**Implementation:** The algorithm begins with the approximation $E_0$ to the *State* equivalence relation $E$. It then repeatedly partitions the equivalence classes until the greatest fixed point ($E$) is reached.

# 19 Hopcroft and Ullman's algorithm

**User function:** *DFA::min_HopcroftUllman*

**Files:** `min-hu.cpp`

**Uses:** *CRSet, DFA, State, StateSet, SymRel*

**Description:** This member function provides a very convoluted implementation of Algorithm 4.7 of [Wat93b]. It computes the distinguishability relation (relation $D$ in [Wat93b]).

**Implementation:** The algorithm is not quite the same as that presented in [Wat93b, Algorithm 4.7]. The member function computes the equivalence relation (on *States*) by first computing distinguishability relation $D$. Initially, the pairs of distinguishable *States* are those pairs $p, q$ where one is a final *State* and the other is not. Pairs of *States* that reach $p, q$ are then also distinguishable (according to the efficiency improvement property given in [Wat93b, Section 4.7, p. 16]). Iteration terminates when all distinguishable *States* have been considered.

**Performance:** This algorithm can be expected to run quite slowly, since it makes use of reverse transitions in the deterministic transition relation (*DTransRel*). The transition relations (*TransRel* and *DTransRel*) are optimized for forward transitions.

# 20 Hopcroft's algorithm

**User function:** *DFA::min_Hopcroft*

**Files:** `min-hop.cpp`

**Uses:** *CRSet, DFA, State, StateEqRel, StateSet*

**Description:** Member function *min_Hopcroft* implements Hopcroft's $n \log n$ minimization algorithm, as presented in [Wat93b, Algorithm 4.8].

**Implementation:** The member function uses some encoding tricks to effectively implement the abstract algorithm. The combination of the out-transitions of all of the *States* is stored in a *CRSet C*. Set $L$ from the abstract algorithm is implemented as a mapping from *States* to **int** (an array of **int** is used). Array $L$ should be interpreted as follows: if *State* $q$ a representative, then the following pairs still require processing (are still in abstract set $L$):

$$([q], C_0), \ldots, ([q], C_{L(q)-1})$$

The remaining pairs do not require processing:

$$([q], C_{L(q)}), \ldots, ([q], C_{|C|-1})$$

This implementation facilitates quick scanning of $L$ for the next valid *State-CharRange* pair.

# 21 A new minimization algorithm

**User function:** *DFA::min_Watson*

**Files:** `min-bww.cpp`

**Uses:** *CRSet, DFA, State, StateEqRel, SymRel*

**Description:** Member function *min_Watson* implements the new minimization algorithm appearing in [Wat93b, Sections 4.6–4.7]. The algorithm computes the equivalence relation $E$ (on states) from below. The importance of this is explained in [Wat93b, p. 16].

**Implementation:** Function *min_Watson* is an implementation of Algorithm 4.10 (of [Wat93b]). The helper function *are_eq* is an implementation of the second algorithm appearing in Section 4.6 of [Wat93b]. Function *are_eq* takes two parameters more than the version appearing in [Wat93b]: $H$ (a *StateEqRel*) and $Z$ (a *SymRel*). These parameters are used to discover equivalence (or distinguishability) of *States* earlier than the abstract algorithm would.

**Performance:** Memoization in function *are_eq* would provide a great speedup.
